

Note on Blobel's Unfolding Method

1 Introduction and notation

The purpose of this note is to clarify the prescription used by Blobel [1] to determine the regularization parameter in unfolding. This involves a succession of transformations of variables such that the new variables have a diagonal covariance matrix. The procedure explained in [1] differs in certain respects from that implemented in the program RUN [2]; the algorithm of RUN is explained in Section 5.

The notation used here is that of *Statistical Data Analysis* [3]. The observed histogram $\mathbf{n} = (n_1, \dots, n_N)$ is regarded as an N -dimensional random vector with expectation values $\boldsymbol{\nu} = E[\mathbf{n}]$. These are related to an M -dimensional “true” histogram $\boldsymbol{\mu} = (\mu_1, \dots, \mu_M)$ by

$$\boldsymbol{\nu} = R\boldsymbol{\mu} + \boldsymbol{\beta}, \quad (1)$$

where R is the response matrix and $\boldsymbol{\beta}$ is a vector of expected background values. Both R and $\boldsymbol{\beta}$ are assumed known.

The goal is to construct estimators $\hat{\boldsymbol{\mu}}$ for the true parameters $\boldsymbol{\mu}$. In regularized unfolding, these are found by minimizing

$$\begin{aligned} \Phi(\boldsymbol{\mu}) &= \chi^2(\boldsymbol{\mu}) + \tau \boldsymbol{\mu}^T G \boldsymbol{\mu} \\ &= (\mathbf{n} - \boldsymbol{\beta} - R\boldsymbol{\mu})^T V^{-1} (\mathbf{n} - \boldsymbol{\beta} - R\boldsymbol{\mu}) + \tau \boldsymbol{\mu}^T G \boldsymbol{\mu}. \end{aligned} \quad (2)$$

Here the covariance matrix of the data $V_{ij} = \text{cov}[n_i, n_j]$ is assumed to be known and τ is the regularization parameter. The symmetric $M \times M$ matrix G can be chosen so that the regularization function $\boldsymbol{\mu}^T G \boldsymbol{\mu}$ corresponds to the average curvature of the solution (see [1, 3]). Here, τ is attached to the regularization function rather than the log-likelihood, as done in [3].

2 The estimators $\hat{\boldsymbol{\mu}}$ for a given τ

For a given value of the regularization parameter τ , the estimators $\hat{\boldsymbol{\mu}}$ are found by setting the derivatives of Φ with respect to the μ_i equal to zero,

$$\nabla \Phi(\boldsymbol{\mu}) = -R^T V^{-1} (\mathbf{n} - \boldsymbol{\beta} - R\boldsymbol{\mu}) + \tau G \boldsymbol{\mu} = 0. \quad (3)$$

The solution is

$$\hat{\boldsymbol{\mu}} = (R^T V^{-1} R + \tau G)^{-1} R^T V^{-1} (\mathbf{n} - \boldsymbol{\beta}) \equiv L(\mathbf{n} - \boldsymbol{\beta}). \quad (4)$$

Since the estimators are linear functions of the data \mathbf{n} , the covariance matrix $U_{ij} = \text{cov}[\hat{\mu}_i, \hat{\mu}_j]$ is found by error propagation to be

$$U = L V L^T. \quad (5)$$

If one considers the special case $\tau = 0$ (the unregularized solution), equation (4) reduces to $\hat{\boldsymbol{\mu}} = R^{-1}(\mathbf{n} - \boldsymbol{\beta})$; this solution will be denoted by $\hat{\boldsymbol{\mu}}_0$.

3 Transforming $\boldsymbol{\mu}$

Consider the function $\Phi(\boldsymbol{\mu})$,

$$\begin{aligned}\Phi(\boldsymbol{\mu}) &= (\mathbf{n} - \boldsymbol{\beta} - R\boldsymbol{\mu})^T V^{-1} (\mathbf{n} - \boldsymbol{\beta} - R\boldsymbol{\mu}) + \tau \boldsymbol{\mu}^T G \boldsymbol{\mu} \\ &= (\mathbf{n} - \boldsymbol{\beta})^T (\mathbf{n} - \boldsymbol{\beta}) - 2(\mathbf{n} - \boldsymbol{\beta})^T V^{-1} R \boldsymbol{\mu} + \boldsymbol{\mu}^T R^T V^{-1} R \boldsymbol{\mu} + \tau \boldsymbol{\mu}^T G \boldsymbol{\mu},\end{aligned}\tag{6}$$

the minimum of which defines the regularized solution. In order to arrive at the prescription for determining τ , one must carrying out three transformations on $\boldsymbol{\mu}$. These are arranged such that the transformed quantities have a diagonal covariance matrix which reduces to the unit matrix for $\tau = 0$. The transformations are:

- (1) an orthogonal transformation, $\mathbf{a} = A\boldsymbol{\mu}$, such that the quadratic term $\boldsymbol{\mu}^T R^T V^{-1} R \boldsymbol{\mu}$ in (6) takes on the form $\mathbf{a}^T B^2 \mathbf{a}$ with B^2 a diagonal matrix;
- (2) a rescaling, $\mathbf{b} = B\mathbf{a}$, such that the quadratic term becomes $\mathbf{b}^T \mathbf{b}$, i.e. $B_{ii} = \sqrt{(B^2)_{ii}}$ and $B_{ij} = 0$ for $i \neq j$;
- (3) an orthogonal transformation, $\mathbf{c} = C\mathbf{b}$, such that the regularization term in (6) can be expressed as $\tau \mathbf{c}^T D \mathbf{c}$ with D a diagonal matrix.

The columns of A are given by the eigenvectors of $R^T V^{-1} R$, the diagonal matrix B is defined by $B^2 = AR^T V^{-1} RA^T$, and the columns of C are given by the eigenvectors of $B^{-1} A G A^T B^{-1}$. Note that one has $\mathbf{b}^T \mathbf{b} = \mathbf{c}^T \mathbf{c}$, since the transformation $\mathbf{c} = C\mathbf{b}$ is orthogonal. The important ingredient here is the matrix D , which is given by

$$D = CB^{-1} A G A^T B^{-1} C^T. \tag{7}$$

After transforming to $\mathbf{c} = CBA\boldsymbol{\mu}$, equation (6) becomes

$$\Phi(\mathbf{c}) = (\mathbf{n} - \boldsymbol{\beta})^T (\mathbf{n} - \boldsymbol{\beta}) - 2(\mathbf{n} - \boldsymbol{\beta})^T V^{-1} R A^T B^{-1} C^T \mathbf{c} + \mathbf{c}^T \mathbf{c} + \tau \mathbf{c}^T D \mathbf{c}. \tag{8}$$

The solution is found by setting the derivatives of Φ with respect to c_i equal to zero,

$$\nabla \Phi(\mathbf{c}) = -2CB^{-1}AR^TV^{-1}(\mathbf{n} - \boldsymbol{\beta}) + 2\mathbf{c} + 2\tau D\mathbf{c} = 0. \tag{9}$$

This gives

$$\begin{aligned}\hat{\mathbf{c}} &= (1 + \tau D)^{-1} CB^{-1} AR^T V^{-1} (\mathbf{n} - \boldsymbol{\beta}) \\ &= (1 + \tau D)^{-1} \hat{\mathbf{c}}_0.\end{aligned}\tag{10}$$

where $\hat{\mathbf{c}}_0$ is the unregularized solution. The covariance matrix $W_{ij} = \text{cov}[\hat{c}_i, \hat{c}_j]$ reduces to the simple diagonal form

$$\begin{aligned}W &= \left[(1 + \tau D)^{-1} CB^{-1} AR^T V^{-1} \right]^T V \left[(1 + \tau D)^{-1} CB^{-1} AR^T V^{-1} \right] \\ &= (1 + \tau D)^{-2}.\end{aligned}\tag{11}$$

Note that the components of $\hat{\mathbf{c}}$ are uncorrelated, since D , and hence also W , is diagonal, and that in particular one has $W = 1$ for the unregularized solution ($\tau = 0$). The standard deviation of the i th component \hat{c}_i is

$$\sqrt{W_{ii}} = \frac{1}{1 + \tau D_{ii}}. \tag{12}$$

4 The number of statistically significant components M_0 and the rule for determining τ

In order to formulate the rule for determining τ , one first needs to introduce the concept of the number of statistically significant components of the unregularized solution. The covariance matrix of $\hat{\mathbf{c}}_0$ is the unit matrix. Therefore, the value of each component \hat{c}_{0i} tells how many standard deviations it is from zero. In [1] Blobel recommends a 95% confidence level corresponding to 1.96 standard deviations. Out of the M components, the number which satisfy

$$|\hat{c}_{0i}| \geq 1.96 \quad (13)$$

is called the number of statistically significant components, M_0 .

For the unregularized estimators $\hat{\mathbf{c}}_0$, the sum of the absolute values of the standard deviations gives the number of components M . The idea for determining τ for the regularized solution is to make the corresponding sum equal to the number of statistically significant components M_0 . That is, τ is defined by the relation

$$M_0 = \sum_{i=1}^M \sqrt{W_{ii}} = \sum_{i=1}^M \frac{1}{1 + \tau D_{ii}}. \quad (14)$$

5 Implementation in RUN

The algorithm actually implemented in the most recent version of Blobel's program RUN [2] is somewhat different from that described above. First, the user is given the option to set by hand the number of statistically significant components M_0 by means of the input keyword **NRDF**, which sets the variable **NDF**. If this is set to zero, then the program uses a default algorithm to determine M_0 , which is, however, different from the algorithm described in the previous section.

If **NDF** is input as zero, then the program first determines a provisional value of τ by solving

$$\begin{aligned} 0 &= \sum_{i=1}^M \left[(\hat{c}_{i0}^2 - \hat{c}_i^2) - 1 \right] \frac{3}{3 + \tau D_{ii}} \\ &= \sum_{i=1}^M \left[\frac{\hat{c}_{i0}^2 (2\tau D_{ii} + \tau^2 D_{ii}^2)}{(1 + \tau D_{ii})^2} - 1 \right] \frac{3}{3 + \tau D_{ii}}. \end{aligned} \quad (15)$$

This is done in the routine **RSOLRT**. According to the comments in the routine, the idea is that the difference $\hat{c}_{i0}^2 - \hat{c}_i^2$ can be considered as the random noise, which should be one per bin. The terms are weighted by the factor $3/(3 + \tau D_{ii})$ in order to suppress larger amplitudes.

This value of τ is then used to compute a provisional (non-integer) number of degrees of freedom (called **XDFR** in **RSOLRT**),

$$x_0 = \sum_{i=1}^M \frac{1}{1 + \tau D_{ii}} \quad (16)$$

This is incremented by one and rounded down to the nearest integer to give M_0 , which is then passed to the routine **RSOLEQ**. There, a new value of τ is determined according to equation (14), as described in the previous section. The statistical test for determining M_0 described in the previous section is not used.

One feature of the program as it stands is that the user may only choose an integer value for M_0 , which leads to a discrete number of choices for τ . One way to bypass this is insert something like

```

if ( set_tau ) then
  tau = user_tau
  goto 20
endif

```

in the beginning of the routine `RSOLEQ`. The logical variable `set_tau` must be set equal to `.true.`, and the real variable `user_tau` set equal to whatever the user wants. These can be brought into `RSOLEQ` via a common block. For a starting value of τ , the default suggested by `RUN` can be used. This procedure seems to work except for extreme cases where one requests a very small τ ; here the program apparently recognizes this as an abnormal condition and returns a much smoother solution than it should. Reasonable variations of τ about its preferred value seem, however, to work.

Another way of allowing for an adjustment of τ would be to modify equation (15) to be

$$0 = \sum_{i=1}^M \left[(\hat{c}_{i0}^2 - \hat{c}_i^2) - \gamma \right] \frac{3}{3 + \tau D_{ii}}. \quad (17)$$

By adjusting γ higher or lower than its default value of unity, the average amount random noise $\hat{c}_{i0}^2 - \hat{c}_i^2$ can be varied. This will result in a different value of x_0 ; if this changes by enough to change M_0 then a different τ will result.
